1. **Summary**

**Public health priority**

Infectious syphilis, confirmed or probable case in a pregnant female: URGENT

Infectious syphilis, confirmed or probable case in a male or non-pregnant female: HIGH

Congenital syphilis: HIGH

Non-infectious syphilis: ROUTINE
### Case management

Immediately on notification of a case of confirmed or probable infectious syphilis, begin follow up investigation and notify the state/territory public health authority.

Cases who present with symptoms consistent with infectious syphilis (a painless, indurated genital ulcer or symptoms / signs of secondary syphilis) must be treated at the time of first presentation.

Cases of infectious syphilis diagnosed on serology should be treated as soon as possible (and ideally within two days) of diagnosis.

For cases of confirmed infectious syphilis of less than two years duration, one dose of benzathine penicillin 1.8g (2.4 million units) by intra-muscular injection (IMI) is required. For probable cases of infectious syphilis or syphilis of more than two years or unknown duration, a course of three doses benzathine penicillin 1.8g (2.4 million units) IMI, 7 days apart, is required.

At the time of the first treatment dose, blood should be collected for (rapid plasma regain test) RPR to provide the baseline used to assess response to treatment and check for re-infection.

RPR testing, by the same laboratory that undertook the baseline assessment, at 3-6 and 12 months following treatment, is important to determine the response of treatment.

Infectious cases are rendered non-infectious 5 days after one dose of benzathine penicillin. Completion of adequate treatment for syphilis does not confer immunity and re-infection can occur.

Particular care is required to ensure adequate treatment in pregnancy, because of the extreme risk of infection to the newborn. Serological follow-up of the maternal RPR during and following the pregnancy is essential. Specialist paediatric advice is recommended if treatment in pregnancy is inadequate and/or if congenital syphilis is suspected.

### Contact management

The aim of identifying contacts of infectious syphilis is to prevent disease transmission by offering testing to identify infection before the onset of clinical symptoms and providing empirical treatment. Timely contact tracing lies at the heart of an effective public health response to syphilis and needs to be prioritised.

Anyone who has had sex (including oral sex) with a person who has confirmed or probable infectious syphilis is a contact. Unborn babies and infants of women with infectious syphilis are also contacts.

For cases with primary syphilis, contacts should be traced for the duration of the case’s symptoms plus three months; if uncertain, contacts to six months prior to presentation, are to be traced.
For cases with secondary syphilis, contacts should be traced for the duration of the case’s symptoms plus six months; if uncertain, contacts to 12 months prior to presentation, are to be traced.

For cases of probable infectious syphilis and early latent syphilis, contacts to one year prior to presentation, are to be traced.

Persons who were sexually exposed to a patient with primary, secondary, or early latent syphilis should be treated presumptively with one dose of benzathine penicillin 1.8g (2.4 million units) regardless of their syphilis serology results.

2. The disease

Infectious agent
The causative agent is the spirochaete bacterium, *Treponema pallidum subspecies pallidum*. There are a number of other *Treponema pallidum* subspecies that cause non-venereal infections including: *pertenue* (yaws), *endemicum* (bejel or endemic non-venereal syphilis) and *carateum* (pinta).

Reservoir
*Treponema pallidum subspecies pallidum* is an obligate human parasite.

Mode of transmission
In the vast majority of cases, syphilis is spread by direct contact with skin lesions or mucous membranes of an individual with infectious syphilis during anal, oral or vaginal intercourse. Vertical transmission can occur at any time during pregnancy and at any stage of syphilis.

Less commonly, syphilis is transmitted by infected blood (transfusion, drug users), by non-sexual personal contact with infected lesions or by accidental direct inoculation.

Incubation period
The incubation period is 10 to 90 days with a median of 3 weeks to the onset of primary syphilis.

Infectious period
Syphilis is most infectious during the primary and secondary stages of the disease (refer section below) when moist mucocutaneous lesions are present, with transmission risk being up to 50% per sexual contact. The infectious period is defined as the first two years of infection, if untreated, however the period of high infectivity lasts for 12 months from the onset of infection. Sexual transmission is uncommon after two years of infection.

The risk of maternal trans-placental transmission to the unborn baby is also highest in infectious syphilis. The risk of infection in the unborn baby of a pregnant woman with primary or secondary syphilis is extremely high, approaching 100%. If left untreated, the risk of vertical transmission diminishes over years but may never disappear.

Infected infants with moist mucocutaneous lesions are a potential source of infection.

Clinical presentation and outcome
Clinical presentation may be highly variable and many cases do not follow the classical stages listed below. Neurosyphilis can occur in any stage of syphilis.

Primary syphilis: The primary lesion, a chancre, begins as a papule 10-90 days after infection, soon ulcerating to form an indurated ulcer at the site of inoculation; this may be on external or internal genitalia or a non-genital site, e.g. lip, tongue, pharynx, anus, rectum. This is usually
painless and accompanied by regional lymphadenopathy. The ulcer heals spontaneously over the course of a few weeks. Clinical suspicion of syphilis should be high for all presentations of a painless, indurated genital ulcer.

Secondary syphilis can follow immediately or occur up to 6 months later. Symptoms include headache, fatigue, adenopathy, low grade fever, sore throat, rash, mucocutaneous lesions, headache, fatigue, condylomata lata (large, raised, whitish or grey, flat-topped lesions found in warm moist areas), alopecia – and these resolve over the course of a few weeks. However, relapses occur in 25% of cases, mainly in the first 12 months.

Early latent syphilis refers to syphilis of less than two years duration (infectious syphilis) in a person who has no symptoms or signs of infection at the time of diagnosis.

Syphilis of more than two years duration, in the absence of clinical signs, is called late latent syphilis. People with late syphilis are asymptomatic for many years. Between one third and one quarter of infected and untreated individuals will ultimately develop tertiary syphilis. The following timelines for development of tertiary syphilis were derived in the pre-antibiotic era and are a guide only. Bone and skin lesions at any time after 2 years but usually between 2 and 15 years, cardiovascular disease at 20-30 years and three types of central nervous system disease (meningo-vascular at 5-12 years, and general paresis and tabes dorsalis usually at 15-25 years).

Treponema pallidum crosses the placenta and infects the fetus at any time in the pregnancy. If untreated, this can result in intrauterine fetal death, stillbirth or a premature baby with congenital syphilis. In early congenital syphilis, the infected baby may be severely affected at birth (with hepatomegaly, ascites, hydrops, fetal anaemia) or more frequently, may appear normal. If the diagnosis is not made then, the baby will present later with non-specific complaints (rhinitis, failure to thrive, pneumonia), nearly always within three months of birth. Neonates with severe disease have a worse prognosis. Late congenital syphilis corresponds to tertiary disease in the adult and can be prevented by early diagnosis and treatment of the infant.

Persons at increased risk of disease

Populations at highest risk of syphilis include Aboriginal and/or Torres Strait Islander people in remote Australia, men who have sex with men (MSM), female partners of MSM and people who have unprotected sex in overseas countries where syphilis is prevalent. Effective treatment of syphilis does not confer immunity against Treponema pallidum, and these high risk groups are at risk of reinfection.

Particular issues of special relevance to MSM and Aboriginal and/or Torres Strait Islander people are discussed in section 12 and Appendix 4, respectively, of this document.

Disease occurrence and public health significance

Syphilis is rare in Australia. However, rates are higher in some communities, including MSM and Aboriginal and Torres Strait Islanders.

National notifications for infectious syphilis more than doubled from 3.0 to 6.7 cases per 100 000 population between 2004 and 2007 after which they declined slightly before returning to 6.7 in 2012.¹ In 2012, infectious syphilis notification rate in males was eight times that of females. These observations reflect high levels of disease transmission among men who have sex with men.¹

In 2012 Aboriginal and Torres Strait Islander people infectious syphilis notifications occurred at five times the rate of non-Indigenous people and outbreaks in remote communities continue to occur.¹

The public health significance of syphilis lies in its impact on the developing fetus in utero and the interaction of Treponema pallidum with the human immunodeficiency virus (HIV). Congenital syphilis is an entirely preventable disease and represents a ‘sentinel health event’. Its occurrence reflects a failure of delivery systems for antenatal care and for syphilis control programs. Syphilis
enhances both the transmission and acquisition of HIV; hence syphilis control is closely allied to HIV prevention.

3. **Routine prevention activities**

A combination of coordinated prevention activities is more effective than an isolated, single activity. Sexual health promotion and education programs aim to increase awareness of sexually transmitted infections (including syphilis) and empower people to adopt safe sex practices thus reducing their risk (e.g. condom use). These programs are targeted to priority groups including young people, MSM, Aboriginal and Torres Strait Islander populations, sex workers and prisoners.

4. **Surveillance objectives**

- Provide baseline data to enable detection of changes in disease trends including evaluation of intervention strategies
- Enable timely detection and identification of cases of infectious syphilis to facilitate rapid response to the management of cases and their contacts
- Enable timely detection of clusters and outbreaks to facilitate early intervention to control transmission
- Inform the prevention of congenital syphilis

5. **Data management**

[Check NCIMS ELR workflows daily for syphilis unspecified cases. Manual entry for new notifications should occur within five working days of notification.]

All new notifications should be checked for duplicates on NCIMS. Possible duplicate syphilis notifications received through ELR are managed by CDB in consultation with PHU’s.

- Where there is sufficient evidence to meet the case definition for confirmed or probable infectious syphilis (e.g. positive PCR from an ulcer, laboratory definitive evidence, or laboratory suggestive evidence and positive IgM) classify/enter the new notification appropriately.
- Where there is insufficient evidence to meet the case definition for confirmed or probable syphilis, classify/enter these new notifications into NCIMS as syphilis unspecified pending collection of enhanced surveillance information.

To assist in identifying subsequent re-infections for previously notified syphilis cases in NCIMS (where subsequent notifications are not notified by ELR), enter the non-specific treponemal antibody tests (e.g. VDRL, RPR) in the laboratory results question package in NCIMS. Note: A 4-fold rise in RPR suggests that the notification represents a re-infection and should be managed in the same way as a new infection.

All syphilis cases should be classified within 90 days of initial notification on NCIMS with the information available to the public health unit. Any additional information received after this time should be added to the NCIMS event and the event should be reclassified if necessary. At least two attempts should be made to obtain enhanced surveillance information to assist correct classification. The valid options for case classification are:

- Syphilis – infectious (probable or confirmed)
- Syphilis >2yrs or unknown duration (confirmed only)
- Congenital syphilis (probable or confirmed)
- Excluded (e.g. doesn’t meet case definition)]
Data for confirmed and probable cases of infectious (i.e. primary, secondary, early latent) syphilis and congenital syphilis should be entered into jurisdictional notifiable conditions databases [NCIMS] within one day of confirmation.

Data for confirmed cases of non-infectious (i.e. late latent, tertiary) syphilis should be entered into jurisdictional notifiable conditions databases [NCIMS] as soon as possible following confirmation.

Syphilis is a notifiable disease under the public health acts of all states and territories, and nationally. Cases of reactive serology are reported by pathology laboratories to public health authorities. In some jurisdictions the medical and/or nurse practitioner who diagnoses a case of syphilis is also required to notify the jurisdictional public health authority.

6. Communications

Notify confirmed and probable cases of infectious (i.e. primary, secondary, early latent) syphilis and congenital syphilis in accordance with jurisdictional statutory requirements [Enter/classify confirmed and probable cases of infectious syphilis in NCIMS; notify CDB of any possible, probable or confirmed congenital syphilis cases] ; include the patient’s date of birth, sex, indigenous status, address, date of onset, laboratory status, possible sources of infection, other people thought to be at risk and follow up action taken.

State/territory Communicable Disease Branches (CDB) should inform CDNA of outbreaks of infectious syphilis. Interjurisdictional outbreaks requiring national coordination may require support from the National Incident Room (NIR). See Appendix 4 for information about outbreaks in remote populations.

7. Case definition

Infectious Syphilis – less than two years duration (includes primary, secondary and early latent)

Reporting

Confirmed and probable cases should be notified.

Confirmed case

A confirmed case requires either:

- Laboratory definitive evidence

or

- Laboratory suggestive evidence and clinical evidence.

Laboratory definitive evidence

- Seroconversion in past two years: treponemal specific test\(^1\) reactive when previous treponemal specific test non-reactive within past two years and the latest result is confirmed by either a reactive non-treponemal test\(^2\) or a different reactive treponemal specific test

or

- A fourfold or greater rise in non-treponemal antibody titre compared with the titre within past two years, and a reactive treponemal specific test

Laboratory suggestive evidence

- Demonstration of Treponema pallidum by darkfield microscopy (not oral lesions), direct fluorescent antibody microscopy (direct antigen test), equivalent microscopic methods (e.g. silver stains), or DNA methods (e.g. nucleic acid testing)
or
  • A reactive treponemal specific test confirmed by either a reactive non-treponemal test or a different reactive treponemal specific test

or
  • A reactive non-treponemal test confirmed by a treponemal specific test

**Clinical evidence**
  • Presence of a primary chancre (or ulcer)

or
  • Clinical signs of secondary syphilis.

**Probable case**
A probable case requires that case does not meet the criteria for a confirmed case and either:

a) In a person with no known previous reactive serology: no history of adequate treatment of syphilis, or endemic treponemal disease, and
  • Contact with an infectious case and laboratory suggestive evidence.
      or
  • Laboratory suggestive evidence and RPR ≥16.
      or
  • Positive syphilis IgM and laboratory suggestive evidence.

or

b) In a person with previous reactive serology: a fourfold or greater rise in non-treponemal antibody titre when the previous serology was done more than two years ago.
    and
    • Contact with an infectious case

or
  • Positive syphilis IgM

a. Treponemal specific tests are: IgG immunoassay, Treponema pallidum haemagglutination assay (TPHA), Treponema pallidum particle agglutination assay (TPPA), Fluorescent Treponemal Antibody Absorption (FTA-Abs), 19S-IgM antibody test, or IgM immunoassay

b. Non-treponemal tests are: Rapid Plasma Reagin (RPR), Venereal Disease Research Laboratory (VDRL)
Syphilis - more than 2 years or unknown duration:

Reporting

Only confirmed cases should be notified.

Confirmed case

A confirmed case requires that the case does not meet the criteria for a case of infectious syphilis less than 2 years duration and either:

Laboratory definitive evidence

or

Laboratory suggestive evidence and clinical evidence.

Laboratory definitive evidence

A reactive treponemal specific test (e.g. IgG immunoassay, *Treponema pallidum* haemagglutination assay, *Treponema pallidum* particle agglutination, or fluorescent treponemal antibody absorption) which is confirmed either by a reactive non-treponemal test (e.g. Venereal Diseases Research Laboratory, Rapid Plasma Reagin) or a different treponemal specific test and

- In a person with no known previous reactive serology: no history of adequate treatment of syphilis, or endemic treponemal disease (e.g. Yaws)

or

- In a person with previously reactive serology: a fourfold or greater rise in non-treponemal antibody titre when the previous serology was done more than two years ago.

Note: In a high prevalence area, only one reactive treponemal specific test result is necessary.

Laboratory suggestive evidence

Demonstration of *Treponema pallidum* by darkfield microscopy (not oral lesions), direct fluorescent antibody microscopy (direct antigen detection), equivalent microscopic methods (e.g. silver stains), or DNA methods (e.g. nucleic acid testing).

Clinical evidence

Clinical, radiological or echocardiographic signs of tertiary syphilis.
Syphilis - Congenital

Reporting

Both confirmed cases and probable cases should be notified, including syphilis-related stillbirth.¹

**Confirmed case**

A confirmed case requires laboratory definitive evidence.

**Laboratory definitive evidence**

Mother and child both seropositive by a treponemal specific test²

and

One or more of the following:

- Direct demonstration of *Treponema pallidum* by any of the following: nucleic acid amplification (NAA) test, dark field microscopy, fluorescent antibody or silver stain - in specimens from lesions, nasal discharge, placenta, umbilical cord, cerebrospinal fluid (CSF), amniotic fluid or autopsy material

  or

- Detection of *Treponema pallidum* specific IgM in the child

  or

- The child’s serum non-treponemal³ serology titre at birth is at least fourfold greater than the mother’s titre.

**Probable case**

A probable case requires laboratory suggestive evidence AND clinical evidence.

**Laboratory suggestive evidence**

- Direct demonstration of *Treponema pallidum* as described under laboratory definitive evidence (above), but without serological confirmation in the child.

  or

- Child seropositive on non-treponemal testing in the absence of IgM testing

  or

- A reactive CSF non-treponemal test (VDRL or RPR) in a child.

  or

- A child who remains seropositive by a treponemal specific test at 15 months of age, which is confirmed either by another, different reactive treponemal specific test or a reactive non-treponemal test, in the absence of post-natal exposure to *Treponema pallidum*, including the non-venereal subspecies *Treponema pallidum* subsp. *pertenue* (Yaws) or subsp. *endemicum* (Bejel, endemic syphilis).
Clinical evidence

- Any evidence of congenital syphilis on physical examination
  or
- Any evidence of congenital syphilis on radiographs of long bones
  or
- An elevated CSF cell count or protein (without other cause)
  or
- The mother is seropositive in the perinatal period AND has no documented evidence of adequate treatment⁴.

Notes:

1. A stillbirth where the foetal death has occurred after a 20 week gestation or in a foetus which weighs greater than 500g should be counted as clinical evidence towards a case where laboratory suggestive or definitive evidence exists.

2. Treponemal-specific tests are:
   - Treponema pallidum immunoassays, *Treponema pallidum* haemagglutination assay (TPHA), *Treponema pallidum* particle agglutination assay (TPPA), Fluorescent Treponemal Antibody Absorption (FTA-Abs) and various IgM assays including 19S-IgM antibody test, or IgM immunoassay.
   - IgM assays should not be used for screening purposes.
   - Treponema pallidum-specific rapid immunochromatography (ICT) assays for use as point-of-care tests are now becoming available, but their performance has not yet been fully established. Positive ICT results should be confirmed with a second treponemal specific assay.

3. Non-treponemal tests are the agglutination assays Rapid Plasma Reagin (RPR) and Venereal Disease Research Laboratory (VDRL). Any positive sera should be tested by serial dilution to provide an end-titre. Non-treponemal tests may be used to monitor efficacy of treatment. Mother and child sera should be collected contemporaneously and tested in parallel and cord blood should not be used for the investigation of congenital syphilis.

4. Treatment is considered adequate if
   - a stage-appropriate penicillin-containing regimen was used 30 days or more prior to delivery and
   - all antenatal and delivery pathology investigations were performed and results verified and
   - there is no evidence of reinfection.

4.1 Treatment with macrolides alone during pregnancy in penicillin-allergic women is no longer regarded as adequate therapy as resistance to macrolides in *T pallidum* is increasingly common and may arise during therapy.

4.2 Although the risk of congenital syphilis is much higher in early-stage disease, in the presence of untreated syphilis the birth of an unaffected child does not guarantee that subsequent children will not be affected.
8. Laboratory testing

Culture is not available. Syphilis is principally diagnosed by serology (treponemal specific and non-treponemal tests), and sometimes (if lesions are present) by nucleic acid amplification techniques or direct demonstration of the organism by dark-field microscopy or direct fluorescent antibody techniques (direct antigen detection).

Syphilis serology

There are two types of syphilis serology tests: treponemal specific tests and non-treponemal tests. Treponemal specific tests detect antibodies specific to treponemal organisms. They become reactive after infection with any treponeme and usually remain reactive indefinitely regardless of adequate treatment. They do not necessarily indicate active infection. Non-treponemal tests detect reagin (a combination of lecithin, cholesterol and cardiolipin), a substance generated by a response to spirochaete-induced damage to cellular membranes. Tests based on detection of antibodies to reagin are a useful indicator of disease activity.

Treponemal and non-treponemal serology tests are less than 100% sensitive in primary syphilis so syphilis serology may be negative in the presence of a chancre.

Treponemal specific tests

- Agglutination assay tests: *T. pallidum* particle agglutination (TPPA), *T. pallidum* haemagglutination (TPHA), microhaemagglutination assay for antibodies to *T. pallidum* (MHA-TPPTPA) shows sensitivity in early syphilis almost equivalent to IgM assays.

- *T. pallidum* immunooassays: enzyme immunoassay (EIA) is suitable for automation and is favoured by many laboratories as a suitable screening test for infectious syphilis. The recombinant (IgG or total antibody) EIA antibody test is probably the most sensitive treponemal specific test post primary syphilis, and it is highly specific. Chemi-luminescent immunoassays (CLIA) eg Abbott Architect are now in wide use and have similar performance to EIAs but occasional false positive results unable to be confirmed with a second treponemal specific assay occur.

- Fluorescent treponemal antibody absorption test (FTA-ABS). Sensitivity varies with disease stage: primary 86%, secondary 100%, early latent 98% and late latent 73%. Specificity is 97%. It is less commonly used as a confirmatory test since the introduction of EIAs and other immunoassays.

- *T. pallidum* IgM EIA: this test is sometimes used in the investigation of congenital syphilis and rarely for early acquired syphilis. Sensitivity is 86.5% in primary syphilis. Sensitivity is low in later disease stages and in re-infection and this test should not be used for screening purposes as occasional low-level false positive results occur. Specificity is 90%.

Non-treponemal tests

- Non-treponemal tests do not detect antibody to *T. pallidum* but to reagin and are a useful indicator of disease activity. Other conditions (infections and autoimmune conditions) can also induce reagin, leading to false positive results but with titres generally ≤ 8. Non-treponemal tests in use today are known as VDRL (venereal diseases research laboratory) and RPR (rapid plasma reagin).

- The VDRL test requires microscopy and is usually used only on cerebrospinal fluid, although it may also be used on serum.
• The RPR is performed on serum or plasma. Sensitivity varies according to disease stage: primary 86%; secondary 100%; early latent 98%, late latent 73%. Specificity is 98% (if treponemal specific tests positive).

**Reporting and interpretation of tests**

There is a period after infection when both treponemal specific and non-treponemal serology may be negative. Generally speaking the treponemal specific test (e.g. EIA) becomes reactive within 2-4 weeks and the RPR becomes reactive within 3-4 weeks post infection.

Most laboratories in Australia now use a treponemal specific test as the first (screening) test following a request for syphilis serology. If reactive, a non-treponemal test (e.g. RPR) and another specific treponemal specific test is performed.

Most laboratories report treponemal specific tests as reactive or non-reactive.

The RPR, if reactive, is reported as a titre – the endpoint of a serial dilution: 1 in 2, 1 in 4, 1 in 8, 1 in 16, 1 in 32 etc. which represents the highest dilution giving a reaction. A higher dilution suggests more active disease. Figure 1, developed by Gavin Hart, indicates the typical RPR response following syphilis infection.

![Figure 1: Variation in RPR titre after infection](image)

The RPR test is also used to monitor response to treatment. A four-fold (or two-titre) drop in RPR e.g. 1 in 128 to 1 in 32 on parallel testing by 6 months is defined as an adequate response to treatment in infectious syphilis though the rapidity of this decline varies according to disease stage (at treatment). This test becomes non-reactive in the majority of patients if infection is diagnosed and adequately treated early in its course. Patients with high RPR titres, late diagnoses and individuals who have been re-infected will be left with fixed reactive RPR titres (e.g. 1 in 16) despite adequate treatment, in up to a quarter of patients.

Re-infection is generally diagnosed on the basis of changes in RPR titre. A four-fold or two-titre rise in RPR, e.g. 1 in 2 to 1 in 8, following previous adequate treatment is considered a re-infection. PCR may be useful if ulcerated lesions are present.

The non-treponemal test results rely on subjective judgements by the operator reading the test. The reproducibility of the result will vary according to the skill of the operator and the antigen preparation used. Comparison of results on serial samples should always be done in parallel. Results from different laboratories for an individual patient should not be compared.

Treponemal specific and non-treponemal tests do not distinguish between sub-species of Treponemes. In some parts of remote Australia yaws and non-venereal endemic syphilis were common up until the late 1960s and yaws remains common in PNG, Indonesia, the Solomon Islands, Vanuatu and parts of central and west Africa. It is possible that people from these regions
who acquired these conditions as children will still have the antibodies giving them reactive treponemal serology without ever having had infectious syphilis.

**Nucleic acid amplification techniques**

If an individual has clinically observable lesions (e.g. genital ulcer, lesions of secondary syphilis), a dry swab for a nucleic acid amplification (NAA) test such as a polymerase chain reaction (PCR) test for *Treponema pallidum* should be collected. This test can also be done on placental specimens (including paraffin embedded tissue) and CSF. These tests are highly sensitive and specific and are now available in most states.

**Point of care rapid tests for syphilis**

The syphilis rapid tests currently commercially available in Australia are SD Bioline™ and Determine™. They both detect antibodies to *Treponema pallidum* and are highly sensitive and specific. A finger-prick (capillary blood), plasma or serum specimen can be used and the result is available within 20 minutes. As with other treponemal specific tests they remain positive indefinitely and will not distinguish between a current infection that requires treatment and past infection (treated or untreated).

Rapid syphilis tests, used in combination with conventional syphilis serology and treatment history data, can facilitate case identification and reduce time to treatment for infectious syphilis. Clear protocols are required for the conduct of the test, for the actions to be taken if the result is reactive, and for the documentation of results. Interpretation requires access to the individual’s previous syphilis serology and treatment history.

If treatment is triggered on the basis of the rapid test alone, then over-treatment can result. In an outbreak situation, this may be considered an acceptable risk.

Point of care rapid syphilis testing has been used with good effect in recent outbreaks in remote Australia, both in the context of community-wide testing and to increase opportunistic testing within primary care services. In the latter setting, the rapid test process must be embedded in work practices within the health service, to be effective.

**9. Case management**

**Response times**

Prioritisation of the public health response to a case of confirmed or probable infectious syphilis is HIGH. Infectious syphilis occurring in a pregnant woman requires URGENT public health response due to the risk of congenital infection. [Respond to possible, probable and confirmed cases of congenital syphilis on the same working day of notification.]

For all other notifications, send a follow up letter and questionnaire to diagnosing doctors within 3 working days of notification.]

**Investigation**

Immediately on notification of a case of confirmed or probable infectious syphilis, begin follow up investigation [In NSW, for any syphilis notification where the patient is managed by a doctor not known to have experience in the management of syphilis, refer the notification to local sexual health services on the day of notification to enable sexual health clinic staff to offer timely assistance to the doctor and complete the notification form. For syphilis notifications where the diagnosing doctor is known to have experience in managing syphilis, send a follow up letter and questionnaire within one working day of notification] and notify the state/territory CDB [Enter/classify case in NCIMS (refer to section 5)].
Public health units may make special arrangements with their sexual health service to facilitate timely and efficient assistance to inexperienced clinicians.

For cases diagnosed by a Sexual Health Service, or clinicians known to the PHU to have expertise in sexual health, the PHU may make special arrangements to facilitate efficient notification and collection of enhanced surveillance information, for example, arranging for distribution or collection of completed forms on a regular basis (at least monthly).]

**Response procedure**

**Case investigation**

**[Congenital cases]**

[The response to a notification will normally be carried out in collaboration with the case’s health carers. Regardless of who does the follow-up, for possible, probable or confirmed cases of congenital syphilis, PHU staff should ensure that action has been taken to:

- Confirm results of relevant pathology tests and presence of symptoms for child and maternal serological test results to determine child meets case definition.
- Complete the congenital syphilis form and forward to Communicable Diseases Branch.
- Refer to appropriate specialist for management]

**[Non congenital cases]**

The response to a notification will normally be carried out in collaboration with the case’s health carers. Regardless of who does the follow-up, for confirmed and probable cases of infectious syphilis, PHU staff should ensure that action has been taken to:

- confirm results of relevant pathology tests
- confirm the onset date and symptoms of the illness
- obtain a full sexual history, including contact history; conduct a physical examination and testing for other STIs, including HIV, in accordance with local clinical guidelines
- find out if the case has had syphilis previously and if so, obtain details of previous syphilis tests and treatments
- find out if the case or relevant care-giver has been informed of their diagnosis and seek the doctor’s permission to contact the case or relevant care-giver (where possible) before beginning the interview; although this may not always be practicable it is included as a courtesy to the treating doctor
- review case and contact management to ensure they have been completed
- review the case history and test results to ensure that the correct syphilis stage has been recorded in notification data.

[Where infectious syphilis is reported in a pregnant woman the PHU staff member is to contact the diagnosing doctor/ medical practice or sexual health service to confirm the woman has returned for treatment or has been referred to specialist services, if appropriate. If the diagnosing doctor has referred the woman elsewhere for treatment (i.e. sexual health), the PHU staff member is to contact the treating service to ensure treatment has occurred.]

**[Cases under 16 years]**

[As Mandatory Reporters, any health worker who has reasonable grounds to suspect that a child or young person may be at risk of significant harm must make an immediate report to the Community Services Child Protection Helpline on 132 117.
Where a case of syphilis is reported in a child <16 years old, the PHU must send a letter to the doctor who requested the test to undertake an assessment of the risk of harm according to the mandatory reporting guidelines and obligations under the Children and Young Persons (Care and Protection) Act 1998.

Where a case of syphilis is reported in a child aged 12 years or under, the PHU must also directly contact the doctor (eg by telephone) to ensure that mandatory reporting obligations have been addressed. If no contact can be made, the PHU should contact the Child Well Being Unit (1300 480 420) or make a direct report to the Community Services Child Protection Helpline (132111).

The PHU should make reasonable attempts to record in NCIMS the Indigenous status of all cases under 16 years, for example by checking the LHD patient management system and/or calling the diagnosing doctor.

All actions should be documented in the NCIMS record.

*Who is the best person to conduct the contact tracing interview?* This is a local decision best made on a case-by-case basis. The culture and gender of the interviewer and whether or not they are known to and trusted by the case are relevant factors to consider.

*When to interview cases about their contacts?* Symptomatic patients should be interviewed in relation to their contacts when they first present, while early latent cases diagnosed on serology findings should be interviewed when seen for treatment.

Interviewing cases about their sexual contacts must be undertaken on a voluntary basis. The cooperation of the case is critical. The interview must be conducted in a private space and without hurrying. It needs to be approached with care and sensitivity and accompanied by clear information in language the individual understands. The way syphilis is spread and the importance of tracing all sexual contacts who may have been exposed should be explained. The case should be assured of the confidential nature of these disclosures and that the contact/s will not be told the identity of the person who named them, only the type of infection to which they have been exposed.

A clinical review at one-week post-treatment is recommended and gives the health care provider the opportunity to ask again about contacts. Even if contact names were provided at the first interview, further careful inquiry would be appropriate, e.g. “….. Is there anyone else you think should be seen?”

When a case has named a contact, they should be asked whether this is their regular partner. If it is, then they should be asked “who else?” If the named contact is not a regular partner, then they should be asked about their regular partner/s. If the interviewer believes there are other contacts that remain un-named, the question may be asked differently. For example, the case may find it easier to remember their contacts if the inquiry is related to significant events: “where were you on your birthday? Did you have a party? Who were you with then?” or “what was happening at the rodeo? Who were you with then?”

The interviewer should always expect more than one contact, and never assume the gender of any contact. The interviewer should also consider asking the case about their friendship group: “who, in your group, do you think should also have a test?” (social contact tracing).

If a case has not named any contacts, or the named contacts do not have syphilis, or a case and contact name only each other, both case and contact must be re-interviewed. Consultation with a local health worker as to the appropriate approach may be helpful, but must not compromise confidentiality.
**Case treatment**

Cases who present with symptoms consistent with infectious syphilis (a painless, indurated genital ulcer or symptoms / signs of secondary syphilis) must be treated at the time of first presentation.

Cases of infectious syphilis diagnosed on serology should be treated as soon as possible (and ideally within two days) of diagnosis. Rapid referral and confirmation of treatment is required if a case moves away from the location where they were diagnosed before undergoing treatment.

Cases of infectious syphilis who are known to be pregnant require urgent follow up and treatment to minimise the possibility of vertical transmission. Breast feeding does not result in the transmission of syphilis, unless an infectious lesion is present on the breast.

The treatment for syphilis generally recommended is long-acting benzathine penicillin.

For cases of confirmed infectious syphilis of less than two years duration, one dose of benzathine penicillin 1.8g (2.4 million units) IMI, OR procaine penicillin 1.5 g IM, daily for 10 days is required. For probable cases of infectious syphilis or syphilis of more than two years or unknown duration, a course of three doses benzathine penicillin 1.8g (2.4 million units) IMI, 7 days apart, OR procaine penicillin 1.5 g IM, daily for 10 days is required.

Cases of congenital syphilis should be treated in consultation with a specialist paediatrician. The recommended treatment is benzylpenicillin 50mg/kg IMI or IVI, 12 hourly for 10 days or procaine penicillin 50mg/kg IMI daily for 10 days.

For detailed information on therapeutic agents for tertiary syphilis see the current edition of *Therapeutic Guidelines: Antibiotics* [www.tg.org.au](http://www.tg.org.au)

If penicillin is contraindicated, seek specialist advice from an infectious diseases, or sexual health, physician. Individuals who are allergic to penicillin should be considered for desensitization in the first instance (especially if pregnant). For non-pregnant patients who are hypersensitive to penicillins if desensitisation is not possible, doxycycline 100 mg orally, 12-hourly for 14 days can be used. Do NOT attempt to treat syphilis with macrolides.

**Monitoring response to treatment**

At the time of the first treatment dose, blood should be collected for RPR to provide the baseline used to assess response to treatment and check for re-infection.

Treatment of infectious syphilis is considered to be adequate if there is a four-fold (two titre) drop in RPR, e.g. 1 in 64 to 1 in 16, by 6 (up to 12) months. RPR testing, by the same laboratory that undertook the baseline assessment, at 3-6 and 12 months following treatment, is important to determine the response of treatment. Comparison of results on serial samples should always be done in parallel. Results from different laboratories for an individual patient should not be compared.

Testing too soon after treatment should be avoided as it may show an increase in RPR; this does not indicate treatment failure.

Infectious cases are rendered non-infectious 5 days after one dose of benzathine penicillin.

Completion of adequate treatment for syphilis does not confer immunity and re-infection can occur.

**Syphilis in pregnancy**

Particular care is required to ensure adequate treatment in pregnancy, because of the extreme risk of infection to the newborn. Treatment of syphilis in pregnancy is according to disease stage and is usually the same as in the non-pregnant state. Contact tracing and treatment for the woman’s partner/s are critical to minimise the potential for re-infection as this represents a particular threat to the unborn baby. Serological follow-up of the maternal RPR during and following the pregnancy is essential and should start at 3 months after the first dose of benzathine penicillin; this is
important for monitoring the response to treatment and prompt detection and treatment of re-infection. For treatment of syphilis in pregnancy to be considered adequate, the first dose must be administered at a minimum of one month (30 days) prior to delivery with a demonstrated four-fold (two-titre) drop in maternal RPR, e.g. 1 in 64 to 1 in 16, prior to birth.\textsuperscript{18} If these conditions have not been satisfied at the time of delivery, then the baby should be examined, investigated and treatment for congenital syphilis considered. Specialist paediatric advice is recommended.

\textit{Education}

Cases of infectious syphilis need to be informed of the infectious nature of their disease, even in the absence of visible lesions or symptoms, and to abstain from sexual activity for 5 days post-treatment or until symptoms have completely resolved (whichever is the longer). The importance of follow up and repeat syphilis serology testing to monitor the response to treatment should be emphasised. The case should be informed that they may continue to have positive treponemal specific tests for life even after successful treatment.

\textit{Isolation and restriction}

Cases of infectious syphilis should abstain from sexual activity for five days after receiving treatment.

\textit{Active case finding}

Testing for syphilis is recommended when:

- There is a clinical presentation of a suggestive genital ulcer (chancre of primary syphilis) or symptoms/signs of secondary syphilis
- A person is diagnosed with another STI – at the time of diagnosis and 3 months later
- A sexual contact of a person diagnosed with an STI is being evaluated
- A person requests an STI check, and
- In pregnancy, according to national and local clinical guidelines. The Royal Australian and New Zealand College of Obstetricians and Gynaecologists recommends syphilis testing of all pregnant women at the first antenatal visit. In Queensland, Northern Territory, South Australia and Western Australia, antenatal care guidelines for remote populations recommend syphilis serology screening 2-4 times during the pregnancy: at the booking visit and again at 28 weeks, and in some jurisdictions at 36 weeks and at delivery. Syphilis testing in pregnancy is essential for early detection and treatment of new infections and re-infections.

Periodic syphilis testing is currently recommended for asymptomatic people in high risk groups, including:

- Young, asymptomatic Aboriginal and Torres Strait Islander populations in specific regions. Recommendations vary between regions and are based on local evidence and expert opinion. Health staff should be aware that the requirement of a blood sample for syphilis testing might deter some young people from participating. Opportunistic syphilis testing of asymptomatic older Aboriginal and Torres Strait Islander people (>40 years) in pursuit of diagnoses of infectious syphilis should be actively discouraged because this group is not at increased risk of infectious syphilis and testing without a clinical indication is likely to result in unnecessary treatment of people with positive treponemal specific tests who were treated many years ago for venereal and/or non-venereal syphilis and/or yaws.

- MSM. The STIGMA (Sexually Transmissible Infections in Gay Men Action Group) guidelines\textsuperscript{5} recommend annual STI testing, including syphilis testing, for all MSM who have had sex with a man in the past one year; 3-6 monthly testing for MSM who have had unprotected anal intercourse, more than 10 partners in the past 6 months, group sex or used recreational drugs during sex; and 3 monthly testing for MSM with HIV.
• Sex workers. STI prevalence in Australian sex workers is low. However, periodic 6-12 monthly testing is recommended.

10. **Environmental evaluation**
Not applicable

11. **Contact management**
It is recommended that jurisdictions ensure that primary health, sexual health and public health staff are made aware of their roles and responsibilities in relation to contact tracing for infectious syphilis. Roles may vary between jurisdictions and between different regions within a jurisdiction. It is also recommended that public health services maintain active oversight of contact tracing processes for infectious syphilis cases even where they do not provide staff to actively support the contact tracing effort. Contact tracing staff should be guided by the Australasian Contact Tracing Manual [http://ctm.ashm.org.au/](http://ctm.ashm.org.au/)

**Identification of contacts**
The aim of identifying contacts of infectious syphilis is to prevent disease transmission by offering testing to identify infection before the onset of clinical symptoms and providing empirical treatment.

**Contact definition**
Anyone who has had sex (including oral sex) with a person who has confirmed or probable infectious syphilis is a contact. Unborn and newborn babies of women with infectious syphilis are also contacts.

How far back to trace? The infectious period depends on the stage of infection.

- For cases with primary syphilis, contacts should be traced for the duration of the case’s symptoms plus three months; if uncertain, contacts to six months prior to presentation are to be traced.
- For cases with secondary syphilis, contacts should be traced for the duration of the case’s symptoms plus six months; if uncertain, contacts to 12 months prior to presentation are to be traced.
- For cases of probable infectious syphilis and early latent syphilis, contacts to 12 months prior to presentation are to be traced.

**Contact management**
In addition to empirical treatment, contact management should include:

- Obtaining a sexual history including inquiry for symptoms or a recent history of symptoms and a clinical examination for signs of syphilis and other STIs
- Investigations for other STIs, according to local clinical guidelines.
- Informing contacts of their test results at the earliest opportunity after the results of investigations become available.
- If it was difficult to locate the contact or if their follow-up is likely to be difficult or delayed, consider obtaining a full sexual history including a sexual contact history at the initial consultation.

Patient and provider referral are the two main methods of alerting contacts. In the former, the case notifies their contacts while in the latter, the health care provider organises the notification and treatment of contacts. In remote populations, provider referral is the principal method of contact tracing used. When patient referral is used, contact management as outlined above should occur.
within two weeks of case treatment and the health staff responsible should confirm with the patient that this has occurred. If delays in patient referral occur, the patient should be offered additional support to undertake patient referral and the option to change to provider referral.

Innovative contact tracing tools have been used in MSM settings. These include on-line patient referral tools such as The Drama Downunder’s ‘Let him know’ website (http://www.thedramadownunder.info/notify/) and the WA AIDS Council M Clinic’s peer-led service delivery. On-line partner notification services have been developed by the Australian Council of AIDS Organisations for Aboriginal people (http://www.bettertoknow.org.au/) and by the Melbourne Sexual Health Clinic (http://www.letthemknow.org.au/).

How much effort should be put into finding contacts of infectious syphilis? The highly transmissible nature of infectious syphilis, and specifically its capacity to spread rapidly through a population and to cause both fetal death and severe congenital complications if transferred to a pregnant woman, demands an urgent response from primary care and public health/sexual health clinic staff. Tracing the contacts of early syphilis should be a high priority, higher than contact tracing for other STI (chlamydia, gonorrhoea) which can cause serious complications but not so acutely. Rigorous and immediate efforts are called for. Half-hearted attempts will result in further sexual transmission and potentially result in serious avoidable outcomes such as congenital syphilis. If contact tracing is not effective, the patient is at high risk of being re-infected after treatment.

**Response times**

Timely contact tracing lies at the heart of an effective public health response to syphilis and needs to be prioritised. Contacts of infectious syphilis who live locally should be seen and treated within two working days of the case’s treatment. If the contacts are elsewhere and referral has been necessary, health staff should aim to ensure that all contacts are seen and treated within two weeks of the case’s treatment.

**Empirical treatment**

Persons who were sexually exposed to a patient with primary, secondary, or early latent syphilis should be treated presumptively with one dose of benzathine penicillin 1.8g (2.4 million units) regardless of their syphilis serology results.

**Education**

Contacts of infectious syphilis need to be informed about the infectious nature of the disease, the possibility that they might be infected and infectious even in the absence of symptoms, and to abstain from sexual activity for 5 days after they have received empirical treatment or their syphilis serology shows that they have not been infected. The importance of follow up and repeat syphilis serology testing to monitor the response to treatment should be emphasised.

**Isolation and restriction**

Sexual contacts of infectious syphilis should abstain from sexual activity for five days after receiving treatment.

**12. Special situations**

Syphilis outbreaks are more likely to occur in particular populations. In Australia, recent outbreaks have occurred in MSM and Aboriginal and Torres Strait Islander populations (See Appendix 4 which comprises Guidelines for the Public Health Management of Syphilis Outbreaks in Remote Populations in Australia). Syphilis clusters may also occur in association with certain sexual networks. It is important to pay attention to confidentiality and the sensitivities associated with sexually transmitted infections when managing syphilis clusters and outbreaks.

MSM who participate in highly sexually active subcultures are at increased risk of acquiring syphilis. Due to the diversity of the MSM population in relation to syphilis infection, any initiative developed must take into account the varying subpopulations, e.g. HIV positive and negative MSM; younger and older MSM (MSM <30 years contribute the highest number of syphilis notifications
among HIV negative MSM whereas MSM aged 40-49 years contribute the highest number of syphilis notifications among HIV positive MSM); and those with differing stages of syphilis including symptomatic and asymptomatic infections. The National Gay Men’s Syphilis Action Plan outlines priority actions to achieve a sustained reduction in the incidence of infectious syphilis in MSM.7

[Management of syphilis cases- referral to sexual health for inexperienced clinicians]

[For all syphilis laboratory notifications where the patient is managed by doctors not known to have experience in the management of syphilis, refer the notification to local sexual health clinic on the day of notification to enable sexual health clinic staff to offer timely assistance to the doctor and complete the notification form.]
Appendix 1. Syphilis Factsheet

What is syphilis?
Syphilis is a highly infectious sexually transmissible infection caused by Treponema pallidum bacteria. If it is not treated syphilis can cause serious health problems. Syphilis can infect both men and women. In NSW, syphilis is most often seen in men who have sex with men.

What are the symptoms?
The symptoms of syphilis depend on the stage of infection; primary, secondary, latent and tertiary.

Primary syphilis
- The first sign of syphilis is a sore or ulcer (called a chancre) which appears at the site of infection. This may be on the penis or other genital area, or in the mouth, vagina, anus or cervix. It is painless and may be hidden from view, and so may not be noticed. It feels firm and round. The chancre usually appears about three weeks after infection, but this can range from 10 days to three months. The chancre lasts three to six weeks and heals spontaneously with or without treatment.

Secondary syphilis
- If primary syphilis is not treated, it progresses to the secondary stage, with rashes, skin lesions, swollen lymph glands, fever, patchy hair loss, muscle and joint aches, headaches and tiredness. These symptoms appear while the chancre is healing or several weeks after it has healed. Characteristically the rash is on one or more areas of the body; red or reddish brown spots appear on the palms of the hands and soles of the feet. Sometimes the rash is on other parts of the body. Large, raised, gray or white warty lumps may develop in warm, moist areas such as the mouth, underarm or groin region.
The symptoms of secondary syphilis can last up to six months. The symptoms disappear with or without treatment. However, without treatment, the person remains infectious and the infection progresses to the latent stage.

Latent syphilis

When the symptoms of secondary syphilis disappear, the disease enters the latent, or hidden, stage. There are no symptoms, but the person is still infected. If syphilis is not treated at this stage it may remain latent for life, or it can develop into tertiary syphilis.

Tertiary syphilis

Tertiary syphilis develops in about 15% of people who have not been treated for syphilis, and can appear 10–20 years after infection was first acquired. In this stage, the disease may involve the brain, nerves, eyes, heart, blood vessels, spinal cord, liver, bones, and joints. Symptoms of tertiary syphilis include difficulty coordinating muscle movements, paralysis, numbness, gradual blindness, heart disease and dementia. This damage may be serious enough to cause death. People are not usually infectious at this stage.

Syphilis in pregnancy

If a pregnant woman has syphilis, the unborn baby may be infected. An infected foetus may die in the womb (stillbirth), or the baby may be born early with or without congenital abnormalities caused by the infection. Untreated babies may become developmentally delayed, have seizures, or die.

How is it spread?

Syphilis is spread during unprotected vaginal, anal or oral sex or through skin-to-skin contact. Syphilis is highly contagious in the first two years after infection, particularly during the primary and secondary stages but also in the early part of the latent stage. Syphilis can be transmitted during pregnancy from a mother to her unborn baby.

Who is at risk?

Everyone is susceptible to infection. In Australia, groups at particular risk of syphilis include:

- men who have sex with men
- female sexual partners of men who have sex with men
- Aboriginal and Torres Strait Islander people
- babies of mothers who have not had adequate antenatal care, including syphilis testing during pregnancy

How is it prevented?

Spread of syphilis can be prevented by:

- consistent use of condoms, dental dams and water based lubricant. Condoms and dams are the best way of protecting against syphilis and some other sexually transmissible infections (STIs)
- avoiding sex with someone who has a visible ulcer or sore on their genitals
- limiting the number of sexual partners to reduce the risk of having sex with someone who has syphilis
- regular STI check-ups.

A person with syphilis should not have sex until five days after their treatment is completed. Sexual partners of someone diagnosed with syphilis should be informed, tested and treated (see treatment below).

All women should have a syphilis test in the first 12 weeks of pregnancy or at the first antenatal visit. Some women should be re-tested later in the pregnancy. Treatment of syphilis early in pregnancy, is very effective in preventing syphilis in the unborn baby. The earlier the infection is treated, the lower the risk that the baby will be affected by syphilis.

There is no vaccine for syphilis.

How is it diagnosed?

Blood tests are used to diagnose syphilis. There is a short period after exposure to syphilis when the tests may not pick up the early stages of infection and repeat tests may be necessary. At this stage, a swab (using a sterile cotton bud) of the chancre can be tested and may detect the infection. A person with syphilis will have a positive blood test by three months after infection, and usually much sooner.

How is it treated?

Syphilis is usually treated with penicillin injections. The length of treatment will vary depending on the stage of infection. Follow-up blood tests may be required to check that the treatment has worked.
People with syphilis should abstain from sexual activity until five days after completing the course of treatment.

People who have had syphilis will always test positive on some blood tests used to diagnose syphilis. People can get re-infected with syphilis after successful treatment. Blood tests can tell the difference between a new infection and one that has been previously treated. Treatment of sexual partners is important to prevent re-infection and to prevent the infection spreading to others.

Doctors should assist a newly diagnosed person to identify and inform all their sexual partners, dating back to the time of infection. Doctors or newly diagnosed people can inform sexual partners. On-line notification websites such as “Let Them Know” (for all people), “The Drama Downunder” (for gay men); and “Better to Know” (for Aboriginal and Torres Strait Islander people) provide advice and assist with informing partners.

What is the public health response?

Laboratories are required to notify cases of syphilis to the local public health unit. This information is confidential. Public health staff use this data to better understand who is at risk and help plan activities to prevent new infections in the future. Patients and their doctors should ensure that sexual partners who may have been exposed to syphilis are contacted for assessment, counseling and treatment.

Further information is available from:

- Sexual Health Infoline (SHIL), a confidential telephone help line: 1800 451 624
- for HIV-positive and HIV negative gay men, [http://www.thedramadownunder.info](http://www.thedramadownunder.info)
- your local Public Health Unit: 1300 066 055 or visit the New Wales Health website [www.health.nsw.gov.au](http://www.health.nsw.gov.au)
Appendix 2. Public health unit checklist

Contact the patient and/or the patient’s doctor to:

- Obtain patient’s risk exposure history
- Obtain patient’s previous syphilis testing and treatment history (this information might be available from a state or regional syphilis register/database)
- Identify likely source of infection
- Confirm onset of symptoms (if any)
- Confirm results of relevant pathology tests
- Ensure that the patient is aware of diagnosis
- Ensure that contact tracing has been commenced.

Contact the laboratory to:

- Check samples received and obtain any outstanding results

Confirm case:

- Assess information against case definition
- Stage syphilis in consultation with specialist advice
- Enter data into jurisdictional infectious disease notification database

Other issues:

Infectious syphilis occurring in a pregnant woman requires a URGENT public health response due to the risk of congenital infection.

**PREVIOUS HISTORY**

1. Has your patient had a negative treponemal test in the last two years? [No] [Yes] [Date] [Unknown]
2. Has your patient been previously diagnosed with syphilis? [No] [Yes] [Unknown]
   - a) When was the most recent diagnosis? [Date]
   - b) What was the most recent RPR or VDRL? [No] [Yes] [Unknown]
   - c) Was the previous infection adequately treated? [No] [Yes] [Unknown]

**SURVEILLANCE INFORMATION**

4. Syphilis classification at the time of specimen collection (see over for definitions):
   - Primary
   - Secondary
   - Late latent (infection > 2 years or at an unknown time)
   - Early latent (infection in last 2 years)
   - Tertiary
   - Congenital syphilis
   - Other (specify)

5. Reason(s) for test:
   - Symptom
   - Contact tracing
   - STI screening
   - Aneural screening
   - Other

6. Did the patient present with signs or report symptoms? [No] [Yes] [Date of onset]

7. Did your patient have a chance? [No] [Yes] [Unknown]
   - if yes, specify the site: [Other]

8. Other signs and symptoms:
   - Generalised lymphadenopathy
   - Neurological symptoms
   - Cardiovascular symptoms
   - Other

9. At the time of diagnosis, was the patient taking HIV pre-exposure prophylaxis (PrEP)? [No] [Yes] [Unknown]

10. Has treatment commenced for new or untreated infections? [No] [Yes] [Date commenced]

**RISK INFORMATION**

11. Did your patient report any of the following sexual exposures? [No] [Yes] [Unknown]
   - Person(s) of opposite sex only
   - Person(s) of same sex only
   - Persons of both sexes

12. Did your patient report contact with a person who had infectious syphilis? [No] [Yes] [Unknown]

13. Has your patient engaged in any sex work in the last 12 months? [No] [Yes] [Unknown]

14. Where was the infection most likely acquired? [NSW] [Australia outside NSW (specify)]

15. From whom was this infection most likely acquired? [No] [Yes] [Unknown]
   - Regular partner
   - Sexual partner
   - Other

16. Where was this patient diagnosed? [No] [Yes] [Unknown]
   - Public hospital
   - Private hospital
   - Family planning

Appendix 4. Guidelines for the public health management of syphilis outbreaks in remote populations in Australia

Outbreak responses will be dictated by the constraints and opportunities within each jurisdiction. These recommendations aim to cover principles to ensure a comprehensive response. Experience has demonstrated that, unlike food-borne or respiratory disease outbreaks, a syphilis outbreak in remote Australia will require a community-wide approach and a sustained response lasting two or more years.¹

A significant syphilis outbreak is a complex social challenge. The ideal response will be multi-strategic, informed by local knowledge, and attentive to detail in its execution. It will be enhanced where positive relationships already exist between the stakeholders.

Syphilis Outbreak Response Framework

A Syphilis Outbreak Response is divided into 4 phases:

**Phase One:** Outbreak identification

**Phase Two:** Early Response (0 – 1 month)

**Phase Three:** On-going Response: Part 1: (1- 12 months); Part 2: (12+ months)

**Phase Four:** Outbreak reporting and response evaluation

<table>
<thead>
<tr>
<th>Public health objectives and targets* for the outbreak response:</th>
</tr>
</thead>
<tbody>
<tr>
<td>The aim of the response is to interrupt the further transmission of infectious syphilis and to prevent congenital syphilis.</td>
</tr>
<tr>
<td>The public health objectives are:</td>
</tr>
<tr>
<td><strong>a)</strong> To achieve best practice management outcomes for cases of infectious syphilis:</td>
</tr>
<tr>
<td>Target: At least 80% of cases are investigated and treated within two weeks of diagnosis</td>
</tr>
<tr>
<td>Target: At least 80% symptomatic cases are examined, tested and treated for syphilis on first presentation</td>
</tr>
<tr>
<td>Target: At least 80% cases of infectious syphilis cases have repeat syphilis serology at 3-6 months post-treatment</td>
</tr>
<tr>
<td><strong>b)</strong> To achieve best practice management outcomes for contacts of infectious syphilis:</td>
</tr>
<tr>
<td>Target: 80% of contacts of infectious syphilis cases are examined, tested and treated for syphilis on first presentation</td>
</tr>
<tr>
<td>Target: 80% of infectious syphilis cases have at least one named contact examined, tested and treated within two weeks of case treatment</td>
</tr>
<tr>
<td>Target: 80% of named contacts are examined, tested and treated for syphilis within one month of being named</td>
</tr>
<tr>
<td><strong>c)</strong> To increase testing in the “at risk” population:</td>
</tr>
<tr>
<td>Target: 100% of antenatal women are tested at first antenatal visit and according to regional clinical guidelines throughout the pregnancy</td>
</tr>
</tbody>
</table>

*The targets are based on discussion with stakeholders and clinical experience
Target: 100% of those diagnosed with another STI (chlamydia, gonorrhea) have a test for syphilis as part of the management of their infection

Approximately 80% of recent infectious syphilis outbreak cases in remote Aboriginal and Torres Strait Islander settings have been in young people under 25 years. Consideration should be given to testing the youth in the affected population for syphilis and the other common STI within 3 months of the start of the outbreak response.
Phase One: Outbreak Identification: Is There a Problem?

It is not possible to provide a specific definition of a syphilis outbreak that can be universally applied. A working definition is: a greater than expected number of infectious syphilis cases diagnosed over a short period within a defined region or sexual network.\(^2,3\) The cases may arise independent of each other or from a single contact tracing effort.

The relevant public health staff should alert their public health medical officer (PH MO) in the event of such an increase over the preceding 3 (up to 6) months.

The PH MO should investigate to determine whether the increase is real and whether there are increases in contiguous regions / jurisdictions. Please note that an increase in testing locally cannot explain away the finding of a cluster of cases of infectious syphilis given that syphilis is no longer an endemic condition in rural / remote populations in Australia.

The initial response requires an immediate re-prioritising of routine work and the allocation of existing staff and resources to address treatment and contact tracing. This situation occurs sporadically across remote Australia, and local services, working collaboratively with regional public health support and expertise, have been able to satisfactorily interrupt further transmission.

If this initial response fails to contain the incident, that is:

- new, un-linked cases continue to be diagnosed, the list of contacts who have not been evaluated increases
- a case of inadequately treated syphilis in pregnancy or congenital syphilis occurs, or
- existing resources are stretched

then a more comprehensive response is called for.

- The relevant PH MO should alert their manager, the Director of the Public Health Unit and their jurisdiction’s Director of Communicable Disease Control. A briefing should be prepared for the attention of the jurisdiction’s Executive Director of Public Health and/or Director General of Health, and the Communicable Diseases Network of Australia (CDNA).
- Each jurisdiction will decide when a briefing to the Minister for Health is appropriate. A briefing should be considered when there are many cases, the outbreak crosses jurisdictional boundaries or involves cases with HIV infection; if an intrauterine fetal death (IUFD) from syphilis occurs, or the outbreak has other features that would attract media attention.

In summary, outbreak identification is a process. Early identification requires:

- A vigilant public health surveillance system including enhanced surveillance for all infectious syphilis cases
- Familiarity with the usual regional epidemiology of syphilis
- Communication between relevant public health staff across jurisdictions
- Clear protocols within public health units for clinical and public health management of infectious syphilis cases.
Phase Two: Early Response

Ideally, these tasks should be completed within the first month.

**Issues to consider**

**A. Governance of outbreak response**

It is essential that an executive position is given explicit responsibility for meeting strategy implementation targets. This responsibility should be accompanied by a set of accountabilities – with consequences for not progressing strategies in a timely manner. At the same time, the accountable party must have the authority to re-prioritize routine service activities in the region. Access to specialist public health and sexual health advice, and the ability to marshal resources to achieve outbreak response targets, are also required.

An outbreak response team (ORT) can improve control efforts by providing leadership, facilitating a co-ordinated, multiagency, partnership approach and giving a central focus to response activities. The partners would include the affected community, local / district health service/s (both government and community-controlled), and population health and sexual health experts. Ideally, each of these groups should be represented on the ORT.

The ORT should be appropriately skilled, authoritative and outcome oriented. It should be responsible for:

- Developing, implementing and evaluating strategies to control the outbreak
- Monitoring and reporting of the outbreak
- Communication with stakeholders and the media
- Attracting additional resources as needed

The agenda for the first ORT meeting should cover the items in the *Phase Two: Early Response* table. A standard agenda for subsequent ORT meetings should include:

- Updates on cases, contacts and their management, including feedback from other jurisdictions when appropriate
- A surveillance report on the outbreak and on syphilis serology testing in the affected population
- Report from senior public health officer (or other suitable officer) on progress in strategy implementation (including condom access) and problems arising
- Individual site reports (where relevant) including community liaison reporting - feedback from community
- Resource requirements: additional staff, funding for community screens

**B. Baseline community, health service and outbreak needs assessment report**

An informed epidemiological and social assessment of the initial cases is needed: the context within which the cases live, the sub-populations most at-risk, the services they can access including local sexual health service capacity and the initial additional resources likely to be required. The report of this assessment should be provided to the first ORT meeting in order to inform intervention development.

**C. Communication with the affected population**

Early face-to-face meetings with local community (and health service leaders) to begin a dialogue, are required. These meetings have the following objectives: to inform and educate community (and health staff); to establish a trusting basis for on-going dialogue; and to seek advice and support for proposed control strategies. A one-on-one relationship between a community representative who supports outbreak control and a suitable person nominated by the ORT, would facilitate on-going communication.

Communication with Aboriginal and Torres Strait Islander people about STI in their communities is always sensitive. Communities care about their health and about the health of unborn children, but the “shame” attached to this issue can overpower these sentiments and elicit a negative response.
Community leaders are necessary partners in addressing a syphilis outbreak. Their co-operation and support is critical to effective intervention. This situation calls for frank explanation and discussion. If the issue is ignored and allowed to fester, the impacts on those affected, and on babies infected in utero, will be felt for years to come. Addressing the situation involves discussion about how to achieve “best practice” in this setting. Sometimes, the most significant barriers to implementing appropriate interventions come not from affected communities but from health staff who, for a variety of reasons, feel challenged by the outbreak, and obstruct “best practice” with arguments about “community” or “cultural” acceptability. These arguments must be overcome.

Engaging early with the state-based peak Aboriginal and Torres Strait Islander community-controlled health organisations should also be considered, as their Board members are usually representative of a broad cross-section of the Indigenous communities in their jurisdiction. This may be particularly useful in opening up communication with difficult-to-reach communities without a community-controlled health service.

D. Communication between public health and clinical staff and services

Periodic communication between neighbouring clinical and public health services (both within and across jurisdictions) is important to quell rumours and enable remote staff to maintain clinical vigilance for their service populations. In addition to clinical communications about the follow up of individuals affected by the outbreak, neighbouring or related health services need updates about the size of the outbreak and where the majority of cases have arisen and/or been diagnosed.

E. Cross-jurisdictional communications

Cross-jurisdictional communication should occur at a number of levels where the affected population spans more than one jurisdiction:

At Public Health Unit level

Cross-jurisdictional communication at this level is a permanent feature of effective syphilis surveillance across Australia. Usually, it occurs by telephone and email as needed. In an outbreak, more frequent communications should be scheduled between the PHNs and PH MOs responsible for syphilis outbreak control. Minutes of these meetings should be tabled at the ORT meeting.

At ORT level

A representative from the affected jurisdictions should sit on (or regularly attend and be briefed by) the ORT of the other jurisdictions involved, so that up-to-date outbreak status information can be readily shared and strategy co-ordination across jurisdictions is made possible.

The ORT should provide timely updates to CDNA.

F. Community communications and media management

The occurrence of a syphilis outbreak is distressing for the individuals affected and for their communities. As noted above, the burden of STIs is in itself a sensitive issue for remote populations who frequently feel judged and at the same time powerless to change the situation.

In the event of a significant syphilis outbreak, both on-going dialogue with community leaders and a community level information campaign is needed to facilitate community co-operation and engagement in the necessary interventions. Communication should focus on the risk of syphilis to individuals and communities, the importance of getting tested, how to keep safe; and the effectiveness of treatment, especially to prevent pregnancy loss and damaged babies.

On the other hand, mainstream publicity about the syphilis outbreak occurring in identifiable Aboriginal and/or Torres Strait Islander communities e.g. regional town newspaper article, is another matter. It carries a significant risk for negative discrimination and will elicit a defensive, counterproductive response from the affected communities.

Hence, responses to mainstream media inquiries must be approached with great care. The language used should be matter-of-fact and the characterisation of the outbreak should not identify locations or particular
populations (e.g. Indigenous) but should be framed in terms of risky behaviours, the importance of safe sex, the value of testing and the curable nature of the condition. Positive pre-existing relationships with a local journalist are always helpful.

Jurisdiction level approval processes for mainstream media messages and press releases should be followed.

G. Additional resources - Staffing

In large outbreaks, a number of locations and regions would be involved and the response will be on-going. In this case, additional staff are likely to be needed for an extended period.

- Skilled sexual health nursing and Indigenous health worker staff
- A senior sexual health promotion officer
- A senior public health officer to lead the on-going implementation of strategies and support outbreak staff. This position would be the link between the ORT and operational staff.

H. Ensuring best practice sexual health services for the at-risk population in health centres in affected locations

Effective, timely case management and contact tracing lie at the heart of controlling an outbreak of syphilis, and these, in turn, rest on sexual health service quality.

- Immediately offer sexual health/public health outreach assistance to the affected health service/s to assist in a review of work practices and information systems supporting sexual health care.
  - What clinical decision support is available?
  - Are data systems in place to support STI clinical management and contact tracing?
  - What STI testing takes place?
- If appropriate on the basis of the findings, offer early assistance to help manage the clinical caseload and address gaps in the service based systems that support sexual health care.
- Support local health service management to organise the delivery (as soon as possible) of a mandatory sexual health skills development package for local staff with review embedded in performance management plans for health workers, nurses and medical officers. The package should focus on confidentiality, respectful communication with patients, increasing testing in at-risk populations, timely treatment of cases and follow up of contacts.
- Inform and engage visiting care providers. This may include a personal letter conveying information about the outbreak, the importance of testing those at-risk and information about syphilis management. Assist these care providers with data feedback on their syphilis testing practices and engage with them to address barriers to increasing syphilis testing.
- Closely monitor testing coverage among local youth, in pregnancy and when another STI is diagnosed, and investigate, if testing fails to increase and health staff insist that young people refuse testing.
- Consider the appointment of a sexual health portfolio holder within the primary care service to oversee STI data systems and to monitor progress against targets.
- Provide feedback to staff on progress in achieving clinical targets.
## Phase Three: On-Going Response

<tr>
<td>2. Establish on-going communication with community leaders of affected population/s</td>
<td>refer issue C above</td>
</tr>
<tr>
<td>3. Establish periodic communication with local and regional health care providers and stakeholders – syphilis factsheet and quarterly outbreak update</td>
<td>refer issue E above</td>
</tr>
<tr>
<td>4. Establish periodic cross-jurisdictional PHU teleconference (if other jurisdictions are likely to be affected)</td>
<td>refer issue I below</td>
</tr>
<tr>
<td>5. Seek additional expert advice:</td>
<td>Expert advice for the ORT</td>
</tr>
<tr>
<td>• Convene a meeting with national Aboriginal and Torres Strait Islander sexual health experts</td>
<td>(refer issue I below)</td>
</tr>
<tr>
<td>• Liaise with state-based peak Indigenous community-controlled health organisations re engaging community and utilizing their public health physician capacity and expertise</td>
<td></td>
</tr>
<tr>
<td><strong>Build clinical sexual health service capacity</strong></td>
<td>Refer issue H above</td>
</tr>
<tr>
<td>6. Implement on-going sexual health skills workforce development (face-to-face and/or video-conference) for primary care staff in affected regions</td>
<td></td>
</tr>
<tr>
<td>7. Ensure adequate STI data systems that facilitate clinical management and contact tracing, are in place in each primary care location</td>
<td></td>
</tr>
<tr>
<td>8. Establish at least one point of reliable condom access 24/7 in each remote location</td>
<td></td>
</tr>
<tr>
<td><strong>Additional strategies to Increase syphilis testing in at-risk population/s</strong></td>
<td>Additional strategies to increase syphilis serology screening in at-risk populations (Refer issue J below)</td>
</tr>
<tr>
<td>9. To increase testing in the at-risk population, implement complementary STI (including syphilis) testing strategies that:</td>
<td></td>
</tr>
<tr>
<td>a. Have community support</td>
<td></td>
</tr>
<tr>
<td>b. Include an evaluation plan</td>
<td></td>
</tr>
<tr>
<td>c. Are based on an understanding of the epidemiology of the outbreak and</td>
<td></td>
</tr>
<tr>
<td>d. Where possible, co-ordinate strategy implementation for related communities within and across jurisdictions</td>
<td></td>
</tr>
<tr>
<td><strong>Sexual health promotion</strong></td>
<td>Sexual Health Promotion</td>
</tr>
<tr>
<td>10. Develop sexual health communications to support the outbreak response.</td>
<td>(Refer issue K below)</td>
</tr>
<tr>
<td>Main messages: Communicate the Risk, Get Tested, Keep Safe (fewer partners, use condoms)</td>
<td></td>
</tr>
<tr>
<td>11. Develop strategies to disseminate these messages widely in affected populations, possibly in schools and among at-risk groups</td>
<td></td>
</tr>
</tbody>
</table>
12. Report the following data for each ORT meeting:

- Management outcomes for infectious syphilis cases and contacts
- Number of new syphilis cases and their connections to known cases, review “outstanding contacts” list and review evaluated contacts’ findings
- If the outbreak is of a manageable size, map cases and contacts and their connections
- Cumulative epidemiological report on outbreak numbers (cases by stage of disease) over time (and by location if multi-focal)
- Syphilis serology test numbers by age group, gender and location
- Syphilis screening guideline adherence (in pregnancy and when another STI is diagnosed) by location

### Part 2: 12+ months

13. Continue 0-12 month activities as outlined above

14. Consider the need for research: Outbreak persistence may indicate the need for new interventions informed by the findings of behavioural and social research on cases and their transmission context e.g. transactional sex among young adolescents

15. Continue to build clinical sexual health service capacity and sexual health promotion capacity including:

- Embedded school based age-appropriate, continuous, curriculum-based sexuality and reproductive health education from year 5 to 10
- Sexual health promotion including community engagement strategies, sexual health communications initiatives, events-based sexual health promotion and consistent condom access.

### Issues to Consider

#### I. Expert advice for the ORT

With respect to the health issue: expertise in population health and sexual health communications, STI epidemiology, remote Aboriginal and Torres Strait Islander primary health care and local health systems, are required.

With respect to the social and demographic context, local knowledge will be critical: an understanding of local sensitivities, local history and the relationships between the Aboriginal and Torres Strait Islander community and the health service.

Access to key individuals from community who are prepared to work with the ORT to negotiate with community how to achieve the outcomes required for an effective response, is needed.

#### J. Additional strategies to increase syphilis serology screening in at-risk populations

In addition to high quality case management and contact tracing, syphilis screening in at-risk populations is a core intervention in the event of an outbreak. Syphilis screening strategies should focus on:
- Adherence to existing guidelines for syphilis screening (in pregnancy and when another STI is diagnosed)

- Increasing syphilis screening in the at-risk population (likely to be youth <30 years) – both opportunistically when they visit the health service and in-community, through out-reach programs to achieve high coverage

- If the outbreak continues with on-going transmission evident in particular locations or networks, then social and behavioural research of cases and the context of transmission may be necessary in order to develop specific interventions to encourage screening for these core-transmitting groups.

In smaller more remote locations, additional syphilis screening strategies may take the form of age group targeted whole of community screening. If this community screening achieves satisfactory participation but the outbreak continues, consider repeating the screen. At-risk individuals in the affected communities will benefit from syphilis testing at a frequency that reflects their risk – more often than annually. Communities are often highly mobile and the resident at-risk population may shift significantly within a six-month period. Furthermore, repeat screens that achieve 70+% participation of the target population resident at the time of the screen may provide useful epidemiological data on the status of the outbreak. It is important to note that the population targeted for STI testing (including syphilis) in a community screen is defined by membership of a high-risk group (young people living in particular locations). In order to exclude a reservoir of infection, the target population for STI screening may include children aged 12-14 years. Performing STI tests for this age group in this context does not constitute grounds for notification to child protection authorities as the tests are provided on public health grounds with no knowledge of an individual’s sexual activity. If the child returns a positive test for an STI, then jurisdiction-level child protection protocols would be followed.

In larger population centres, strategies to increase syphilis serology screening in young people attending primary care and sometimes, emergency departments of public hospitals, are utilised.

K. Sexual Health Promotion

The term sexual health promotion covers a broad range of activities that are best conceptualised using the Ottawa Health Charter Framework. This approach emphasizes working with communities to improve the conditions that determine sexual risk for youth, and it includes: reorienting health services, community engagement strategies, population-wide sexual health communications, school-based sexuality and relationships education, and improvements in condom access. Building this broad sexual health promotion capacity will be critical for sustainable and continuing improvements in sexual health outcomes.

However, in the context of a syphilis outbreak, the immediate sexual health promotion priorities will be to implement effective youth screening recruitment strategies, to develop relationships that facilitate constructive community dialogue, to establish consistent condom availability, and sexual health communications. The latter is of the highest priority with the main messages being:

- Communicate the risk

- Get tested, and keep safe
## Phase Four: Outbreak Reporting and Response Evaluation

### Phase Four: reporting and evaluation

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>16.** Decide when the outbreak is over:**</td>
<td><strong>Issues to consider</strong></td>
</tr>
<tr>
<td></td>
<td></td>
</tr>
<tr>
<td>- No strict criteria exist. Ideally, the number of new infectious cases reduces to pre-outbreak levels while at the same time the at-risk population testing coverage is high.</td>
<td></td>
</tr>
<tr>
<td>- Unfortunately, it may be that notifications reduce but only to a level that is higher than before the outbreak (indicating low level endemicity).</td>
<td></td>
</tr>
<tr>
<td>- For the outbreak to be declared over, the caseload must be within a range that can be managed within permanently available sexual health resources.</td>
<td></td>
</tr>
<tr>
<td>17.** Develop a report that describes the epidemiology of the syphilis outbreak and the outbreak response**</td>
<td></td>
</tr>
<tr>
<td>18.** Evaluate the outbreak response**</td>
<td>Outbreak evaluation**(refer issue L below)**</td>
</tr>
<tr>
<td>- Both process and outcome measures should be used in the evaluation.</td>
<td></td>
</tr>
<tr>
<td>- An outbreak evaluation report should be produced and disseminated so that lessons can be learned and these guidelines refined.</td>
<td></td>
</tr>
</tbody>
</table>

### Issues to consider

#### L. Outbreak evaluation

Process measures will depend on the interventions employed and may include:

- Timeliness of outbreak identification and response development
- Satisfaction of community and other partners
- Condom access measures
- Assessment of testing coverage of specific at-risk populations, in pregnancy, and for those diagnosed with another STI, against targets (see Public Health Objectives and Targets for the Outbreak Response)
- Assessment of management outcomes for cases and contacts against targets (see Public Health Objectives and Targets for the Outbreak Response)
- Measures arising from specific interventions e.g. coverage of target population in community screens
- Measures arising from sexual health promotion interventions

The primary outcome measure is the reduction in the number of cases of infectious syphilis diagnosed.
